1. Introduction

A nonconventional cooling-combustion engine uses the part of energy bound in a cooling system of a combustion engine for production of the cooling output applicable in vehicles (see Fig. 1) [2].

An engine cooling liquid is replaced by mixture of the lithium bromide liquid with water [6]. The solved energetic system is defined in area of trigeneration systems. The mentioned system is a source of electrical energy, cold and heat. The engine used in the system is four stroke compression ignition engine Z8004 with rated power of 77 kW at 2200 min⁻¹. The heat produced by the engine cooling system is pulled into the absorption cooling equipment.

The article shows the flow simulation of the working medium in this structural shape of vaporization container of a cooling circuit of the nonconventional combustion engine. The problem with vaporization container was that the off-take wasn’t able to take away the entire needed amount from the evaporator.

2. Definition of the model and the flow simulation

The CAD software used for the model creation is CATIA V5 [2]. The model of the whole evaporator can be seen in Fig. 2.

For the purpose of simulation we used only one half of this space because of the symmetry of the geometry which allows for...
decrease in the requirements for the used hardware and computational time.

Fig. 3 shows the mesh in the area of the bottom outlet. Then the suitable types of boundary conditions are applied to the mesh model (see Fig. 4). The resulting mesh contains about 480 000 elements [5].

Next step was the definition of the computational model. Values for the boundary conditions were set. The RNG $k-e$ turbulent model was used for the flow simulation. This model is robust enough and suitable for the solution of turbulent flows and heat transfer [4]. The renormalized procedure consists of a gradual elimination of narrow bands of wave numbers. Equations of motion are transformed so that turbulent viscosity, forces and nonlinear members are modified. Assuming that the turbulences are related to dissipation $\varepsilon$, then, the turbulent viscosity $\mu_t$ depends on a degree of turbulences and the RNG method constructs this viscosity with the help of iterative elimination of narrow bands of wave numbers. The following equation is used for the iterative process [1 and 5]:

$$\frac{d\mu_t}{dt} = A_\varepsilon \varepsilon \frac{l}{\mu,l}$$  \hspace{1cm} (1)

The RNG model derived by a statistical method, averaged, is formally of the same form as the classical $k-e$ model. The equation for the transfer of motion is in the form:

$$\frac{\partial}{\partial t}(\rho u_i) + \frac{\partial}{\partial x_j}(\rho \bar{u}_i \bar{u}_j) =$$

$$- \frac{\partial}{\partial x_j} \left( K_{ij} \frac{\partial \bar{u}_i}{\partial x_j} + \frac{2}{3} \frac{\partial \bar{u}_j}{\partial x_j} \right) - \frac{\partial p}{\partial x_j} + \rho g_i + F_i$$  \hspace{1cm} (2)

and, subsequently, transport equations are used:

$$\frac{\partial}{\partial t} (\rho k) + \frac{\partial}{\partial x_j} (\rho u_j k) =$$

$$= \frac{\partial}{\partial x_j} \left( \alpha_{eff} \mu \frac{\partial k}{\partial x_j} \right) + \mu_S S^2 - \rho \varepsilon$$  \hspace{1cm} (3)

$$\frac{\partial}{\partial t} (\rho \varepsilon) + \frac{\partial}{\partial x_j} (\rho u_j \varepsilon) =$$

$$= \frac{\partial}{\partial x_j} \left( \alpha_{eff} \frac{\partial \varepsilon}{\partial x_j} \right) + C_{\mu\varepsilon} \mu S^2 - C_{\mu\varepsilon} \frac{\varepsilon^2}{k} - R$$  \hspace{1cm} (4)

Time step was set to 0.001 s. The velocity in the inlet was set to 0.68 m.s$^{-1}$. Fig. 5 shows the level of the cooling liquid at the start of the simulation process (1 cm under the edge of the evaporator cone).

3. Achieved results

The filling of the evaporator ring by the cooling medium is shown in Figs. 6, 7, 8 and 9. The off-take is able to take away the
entire needed amount from the evaporator. The simulation shows that the lithium bromide liquid starts to pour through the edge of the evaporator cone in the time of about 0.96 s after the initiation of the calculation. The starting cooling liquid level has the value of 1 cm under the edge of the evaporator cone. The value of 1 cm is used because of the decrease in the computational time.

The found value of 0.96 s valid for the 55 % lithium bromide liquid cannot be experimentally verified by means of simulation due
to the fact that water is at present time the coolant in the cooling circuit of the engine.

Figs. 10 and 11 illustrate that the maximal values of turbulence intensity are situated in the area of cylindrical walls of the inflow and outflow pipes, edge of the evaporator cone and at the lithium bromide liquid level in the centre of the evaporator [5].

4. Conclusion

The simulation shows that the cooling medium starts to pour through the edge of the evaporator cone in the time of about 0.96 s after the simulation starts. The inflow and outflow pipes, edge of the evaporator cone and the area of the coolant level in the evaporator centre are the places of the turbulent intensity maximal values.
